Abstract. This paper compares the equilibrium properties of FAST TCP and TCP Vegas. Although the two have the same equilibrium point when all sources know their true propagation delays, FAST is fairer when there are estimation errors. The performance of Vegas approaches that of FAST when the queueing delay is very much less than the propagation delay.

1 Introduction

Given the importance of controlling congestion and stability of the Internet, there have been many proposals aiming to improve the well known TCP Reno protocol [4]. Two such popular proposals that have received significant attention in recent years are TCP Vegas [1, 2] and FAST TCP [6–8]. This paper compares these two TCP versions from the point of view of fairness in equilibrium.

TCP Vegas and FAST TCP aim to improve throughput and fairness over their predecessors, the most popular of which is TCP Reno, by using queueing delay as a congestion signal because queueing delay provides a finer measure of congestion and scales more naturally with network capacity than packet loss probability does [7].

Because both FAST TCP and TCP Vegas use queueing delay as a congestion signal, their window updating algorithms rely on knowing the propagation delay, which is estimated by a measure called baseRTT. This measure is defined as the minimum round-trip time (RTT) observed so far. Because sometimes the routers’ queues never become empty, the actual propagation delay may be inaccurately estimated by baseRTT which results in unfairness [7, 11], and excessive variations of routers’ queues.

Considering steady state (equilibrium) conditions, the aim of this paper is to analyse and compare the fairness of FAST TCP versus TCP Vegas. However, it is important to clarify at the

* This work was supported by the Australian Research Council
outset a certain confusion that one may encounter considering the definition of TCP Vegas. A certain ambiguity exists in this definition and there are two interpretations of TCP Vegas, one of which makes TCP Vegas very similar to FAST TCP. In particular, TCP Vegas uses queueing delay as the congestion signal which is different from TCP Reno. It is parameterised by a rate $\alpha$. As pointed out in [10], the original description of Vegas [2] was ambiguous about whether $\alpha$ measures the rate per second, or per round trip time. In this paper, the term “Vegas” will be used for the form analysed in [10] (specifically, Section 4.2 of [10]). This matches the prose description in [2], in which $\alpha$ is the rate per second. Where ambiguity may arise, it will be called “the prose version of Vegas”. The term “FAST” will be used for the the form adopted by FAST TCP [7], which matches the implementation of Vegas, in which $\alpha$ is the rate per round trip time. As we consider equilibrium conditions, we ignore the slow start phase for both Vegas and FAST TCP in this paper.

The structure of this paper is as follows. In Section II, we define the notation for this paper, in Sections III, IV and V, we introduce the TCP Vegas and FAST TCP algorithms in detail. In Section VI, we analyse the fairness of the two TCP protocols and in Section VII, we use simulation to verify the analysis.

2 Notation

Let $L(i)$ denote the set of links used by flow $i$. Let $d_i$ [seconds] be the true propagation delay of flow $i$, let $\hat{d}_i = d_i + \delta_i$ be the estimated propagation delay, and let $D_i(t) = d_i + q_i(t)$ be the round trip time of flow $i$, including queueing delay of $q_i(t)$. Let $w_i(t)$ [packets] and $x_i(t)$ [packets/s] be the window size and rate for flow $i$, which are related by

$$w_i(t) = x_i(t)D_i(t).$$

(1)

Let $c_l$ [packets/s] be the capacity of link $l$, and $b_l(t)$ [packets] be the backlog at link $l$.

Quantities without explicit time dependence are either constants or equilibrium values; for example, $b_l$ is the equilibrium backlog at link $l$.

Both FAST and Vegas use a parameter called $\alpha$, although the meaning of each is subtly different, as alluded to in the introduction. Flows using FAST and Vegas aim to keep a fixed number of packets in queues throughout the network. Under FAST, flow $i$ aims to keep $\alpha_i$ packets, while under Vegas it aims to keep $\alpha_i d_i$. To avoid confusion, the alpha values for Vegas will be denoted $\alpha^+$. Comparisons in this paper will use the following scenario, called Persistent Congestion in [10]. All flows share a single bottleneck link of capacity $c$ [seconds], have equal $\alpha$ [packets] (or $\alpha^+$ [packets/s]), and have equal propagation delays, $d$ [seconds]. Flows arrive consecutively, spaced far enough apart for the system to reach equilibrium between arrivals, and keep transmitting greedily and persistently. When the $i$th flow arrives, it causes the queue size at the bottleneck link to increase by $B(i)$ [packets]. If $d$ were known exactly, then $B(i)$ would be $\alpha$ under FAST, or $\alpha^+ d$ under Vegas. However, the estimate $\hat{d}$ will be assumed to be the RTT seen when the flow first arrives, given by $d(i) = d + p(i - 1)$ [seconds], and $B(i)$ will consequently be larger. Here $p(i) = \sum_{j=1}^{i} B(j)/c$ [seconds] is the total queueing delay after the arrival of flow $i$.

To distinguish between the equilibrium of FAST and of Vegas, quantities pertaining to Vegas will have a superscript $+$.
3 Equilibrium conditions of Vegas

As we ignore the slow start phase, for Vegas parameters of $\alpha_i^+$ and $\beta_i^+$ for flow $i$, the update rule for Vegas [2] can be expressed as

$$w_i(t+1) = \begin{cases} w_i(t) + \frac{1}{D_i(t)} & \text{if } \frac{w_i(t)}{d_i} - \frac{w_i(t)}{D_i(t)} < \alpha_i^+ \\ w_i(t) - \frac{1}{D_i(t)} & \text{if } \frac{w_i(t)}{d_i} - \frac{w_i(t)}{D_i(t)} > \beta_i^+ \\ w_i(t) & \text{otherwise} \end{cases}$$  

(2)

Recall the equilibrium results for Vegas, derived in [10], when the $i$th flow estimates its propagation delay by $\hat{d}_i$, and $\beta_i^+ = \alpha_i^+$. A Vegas flow is in equilibrium if

$$\alpha^+ \hat{d}_i = w_i \left(1 - \frac{\hat{d}_i}{D_i}\right).$$  

(3)

The equilibrium state of Vegas maximises the sum of the flows’ utilities, where the utility of flow $i$ is

$$U_i(x_i) = \alpha_i^+(d_i + \delta_i) \log x_i + \delta_i x_i.$$  

(4)

Under Persistent Congestion, the increments in queue occupancy, $p^+(i)$, satisfy

$$\sum_{j=1}^{i} \frac{d + p^+(j-1)}{p^+(i) - p^+(j-1)} = \frac{c}{\alpha^+}$$  

(5)

with

$$p^+(1) = \frac{\alpha^+ d}{c}$$  

(6)

and the rate of flow $j$ between the arrival of flow $i$ and flow $i+1$ is

$$x_j^+(i) = \frac{\alpha^+(d + p^+(j-1))}{p^+(i) - p^+(j-1)}.$$  

(7)

Analogous results will now be derived for FAST.

4 Utility function of FAST

The update rule for FAST can be written as [7]

$$w_i(t+1) = \gamma \left( d_i w_i(t) + \alpha \right) + (1 - \gamma)w_i(t)$$  

(8)

for some constant $\gamma \in (0, 1]$, giving the equilibrium condition

$$\alpha = w_i \left(1 - \frac{\hat{d}_i}{D_i}\right).$$  

(9)

(Note that this rule also applies if Vegas adapts its $\alpha^+$ to its estimate of $d_i$ in an attempt to achieve proportional fairness [10]. In that case, $\alpha^+ := \alpha/\hat{d}_i$.)
By arguments analogous to [10], it can be shown that the FAST equilibrium maximises the sum of flows’ utilities, where the utilities are now given by

\[ U_i(x_i) = \alpha_i \log x_i + \delta_i x_i. \]  

(10)

The core argument is to show that the derivative of the utility of flow \( i \) is the sum of suitable Lagrange multipliers, \( p_l \), corresponding to the price of each link, evaluated at the equilibrium. That is,

\[ U_i'(x_i) = \frac{\alpha_i}{x_i} + \delta_i = \sum_{l \in L(i)} p_l. \]  

(11)

That can be seen as follows. The number of packets queued by flow \( i \) at link \( l \) is \( b_l x_i/\epsilon_l \). The total number of packets queued by flow \( i \) in equilibrium is

\[ \sum_{l \in L(i)} \frac{b_l x_i}{\epsilon_l}. \]  

(12)

Since the total number of packets from flow \( i \) in flight, \( w_i \), is equal to the sum of those in propagation, \( x_i \hat{d}_i \), and those queued, in equilibrium

\[ w_i - x_i \hat{d}_i = \sum_{l \in L(i)} \frac{b_l x_i}{\epsilon_l}. \]  

(13)

Combining (1), (9) and (13) gives

\[ \alpha_i = w_i \left(1 - \frac{\hat{d}_i}{\hat{D}_i}\right) = w_i - x_i (\hat{d}_i + \delta_i) = \sum_{l \in L(i)} \frac{b_l x_i}{\epsilon_l} - \delta_i x_i. \]  

(14)

Rearranging and setting \( p_l = b_l/\epsilon_l \) yields (11), as required.

5 FAST under Persistent Congestion

On the surface, it seems that (4) and (10) are equivalent under the substitution \( \alpha_i = \alpha_i^+ \hat{d}_i \). However, it turns out to be very significant that the number of packets that Vegas attempts to maintain in the queue, \( \alpha_i^+ \hat{d}_i \), depends on the error in the estimate of the propagation delay. To see that, consider the equations for persistent congestion analogous to (5) and (7), which will now be derived, following [11].

The equilibrium rates satisfy

\[ x_1 + x_2 + \ldots + x_i = c, \]  

(15)

and

\[ x_j = \alpha /q(j), \]  

(16)

where \( q(j) \) is the queueing delay as observed by flow \( j \). When there is only one flow in the link, this yields \( x_1 = c, \) and \( q(1) = B(1)/c. \) Using (15) and (16) we have \( B(1) = \alpha \) and \( p(1) = \alpha /c \). When the second flow enters the link, it estimates \( \hat{d}(2) = d + B(1)/c \), and perceives a queueing delay of \( q(2) = B(2)/C \), while the first flow sees the true queueing delay of \( q(1) = \)}
\( (B(2) + B(1))/c. \) Again using (15) and (16) gives \( 1/(B(1) + B(2)) + 1/B(2) = 1/\alpha \) and \( 1/p(2) + 1/(p(2) - p(1)) = c/\alpha. \) By induction,

\[
\sum_{j=1}^{i} \frac{1}{p(i) - p(j - 1)} = \frac{c}{\alpha}
\]

and the rate of flow \( i \) between the arrival of flow \( i \) and flow \( i + 1 \) is

\[
x_{j}(i) = \frac{\alpha}{p(i) - p(j - 1)}.\tag{18}
\]

Note that, unlike (5) and (7), these expressions are independent of \( d. \) If \( d >> p^+(j) \) for all \( j, \) then the queueing delay and rates of Vegas reduce to those of FAST (with the substitution of \( \alpha^+d = \alpha). \) However, if \( p^+(j) \) is not negligible, the results differ.

6 Comparison of FAST and Vegas

Since the equilibria are different, the question arises: which is fairer?

When \( i = 2, \) (5) for Vegas becomes

\[
\frac{d}{p^+(2)} + \frac{d + p^+(1)}{p^+(2) - p^+(1)} = \frac{c}{\alpha^+} = \frac{d}{p^+(1)}
\]

(19)

giving

\[
p^+(2) = \frac{3d + p^+(1) + \sqrt{(3d + p^+(1))^2 - 4d^2}}{2d}\]

\[
= \frac{3d + p^+(1) + \sqrt{(d + p^+(1))(5d + p^+(1))}}{2d},
\]

where the \( \pm \) becomes \( + \) since otherwise \( p^+(2) < p^+(1), \) which is not possible. The rate of the worse-off flow for Vegas is thus

\[
x_{1}^+(2) = \frac{\alpha^+d}{p^+(2)} = \frac{2c}{3 + \alpha^+/c + \sqrt{(1 + \alpha^+/c)(5 + \alpha^+/c)}}
\]

(21)

which is clearly less than

\[
x_{1}(2) = \frac{2c}{3 + \sqrt{5}}
\]

(22)

yielded by FAST.

Note that this trend continues, and FAST is fairer than Vegas for any number of sources. More specifically, if \( \alpha^+d = \alpha, \) then \( p^+(i) > p(i) \) for all \( i > 1. \) Furthermore, \( x_{i}^+(i) < x_{i}(i) \) for all \( i > 1 \) and all \( \alpha, \alpha^+. \) For \( i = 2, \) this follows from (21) and (22). The result can then be shown by induction on the hypothesis \( p^+(j) > p(j) \) for all \( 1 < j < i. \) To see that this implies \( p^+(i) > p(i), \) assume instead that \( p^+(i) \leq p(i). \) Then \( p^+(i) - p^+(j - 1) < p(i) - p(j - 1), \) whence

\[
\frac{c}{\alpha^+} = \frac{d}{p^+(1)} + \sum_{j=2}^{i} \frac{d + p^+(j - 1)}{p^+(i) - p^+(j - 1)} > \frac{d}{p^+(1)} + \sum_{j=2}^{i} \frac{d + p^+(j - 1)}{p(i) - p(j - 1)}
\]

\[
> \frac{d}{p(1)} + \sum_{j=2}^{i} \frac{d}{p(i) - p(j - 1)} = \frac{c}{\alpha/d}
\]
where the second inequality uses \( p(1) = p^+(1) \). This contradiction establishes \( p^+(i) > p(i) \).

Since \( p(0) = 0 \), (7) and (18) show that, for this \( \alpha \), \( x^+_1(i) < x_1(i) \). However, \( x_1(i) \) is independent of \( \alpha \) by (18), since \( p(i) \propto \alpha \). Thus \( x^+_1(i) < x_1(i) \) for all \( i > 1 \) in general.

This finding has two implications. On one hand, it shows that the prose version of Vegas is less fair than FAST and the implemented form of Vegas. On the other, it shows that persistent congestion is less of a problem than is predicted by the analysis of [10].

The authors of Vegas suggested using small values of \( \alpha \). However, the optimal value is difficult to set in practice. If it is too small, then the queueing it induces in a high speed link may be small compared to the jitter of round trip times, making measurement inaccurate. Hence, a large value must often be used, as is proposed for FAST [6]. However, if such an \( \alpha \) is used over a low capacity link, it is possible for \( \alpha^+/c \) to be large. As \( \alpha^+/c \) becomes large, Vegas becomes arbitrarily unfair. In the case of two sources,

\[
x^+_1(2) < \frac{c}{2 + \alpha^+/c} \to 0.
\]

Consider also the inductive hypothesis (in \( i \)) that \( p^+(j) >> p^+(k) >> d \) for all \( k < j \leq i \). This is true for \( i = 1 \) by (6), when \( \alpha^+/c >> 1 \). Then (5) becomes

\[
\frac{p^+(i-1)}{p^+(i)} \approx \frac{c}{\alpha^+} << 1,
\]

showing that \( p^+(i) \approx d(\alpha^+/c)^i \) for all \( i \). Thus, by (7), the most recently arriving flow obtains almost all of the capacity. Although this case is pathological, it is in principle possible under Vegas. However, it cannot occur under FAST, since \( p(i) \) is independent of \( d \).

This scaling of Vegas is in contrast to that of FAST. Although \( B(k) = (p(k) - p(k-1))c \) are known to diverge [11], they diverge slower than any power of \( k \). To see that, assume instead that there exist an \( \eta > 0 \) and \( \gamma > 0 \) such that \( B(k) > \eta k^\gamma \) for all \( k \). Approximating sums by integrals in (17) gives

\[
\frac{1}{\alpha} = \sum_{j=1}^{i} \frac{1}{\sum_{k=j}^{i} \eta k^\gamma} \\
\approx \frac{\gamma + 1}{\eta} \sum_{j=1}^{i} \frac{1}{i^{\gamma+1} - (j-1)^{\gamma+1}} \\
\approx \frac{\gamma + 1}{\eta} \left( \frac{1}{i^{\gamma+1}} + \sum_{j=2}^{i} \frac{1}{i^\gamma (i-j+1)(\gamma+1)} \right) \\
= O \left( \frac{\log(i)}{i^\gamma} \right) \to 0.
\]

However, \( \alpha \) is a constant, which is a contraction and shows that there is no positive power of \( k \) that \( B(k) \) consistently grows faster than.

Empirically, it appears that \( B(i)/B(1) = \log(i) + o(1) \). This can be seen in Figure 1, which plots \( B(i)/B(1) - \log(i) \). If this is indeed the case, then the lowest throughput of any source is \( B(1)/(B(1) + \ldots + B(i)) = O(1/i \log(i)) \).
7 Simulation Results

To verify the above analysis, we consider a persistent congestion scenario with 10 flows. The bottleneck link bandwidth is 100 Mbps (= 12500 packet/s), and the round trip propagation delay is 40 ms (20 ms each way). Simulations were performed using ns2 [9] disabling the slow start phase. The Vegas module in ns2 interprets \( \alpha \) as the rate per propagation delay, as FAST does. The results presented here for “Vegas” were obtained by modifying the code to implement the prose version of Vegas. The FAST implementation was [3]. We measure the queue size and every source’s stable rate for three flow control rules: FAST (\( \alpha = 200 \) packet), Vegas with \( \alpha^+ = 250 \) packet/s and Vegas with \( \alpha^+ = 2475 \) packet/s. For Vegas, \( \beta = \alpha + 25 \) packet/s; we chose \( \alpha^+ < \beta^+ \) to prevent oscillation [2]. These induce additional queuing delays of approximately \( \alpha^+ d/c = 0.4 \) ms and 4 ms, respectively.

To validate (5) and (17), we compare the actual simulation rates with theoretical analysis for FAST (in Figure 2), Vegas with \( \alpha^+ = 250 \) packet/s (in Figure 3) and Vegas with \( \alpha^+ = 2475 \) packet/s (in Figure 4) for the second and sixth sources. The results match almost perfectly for FAST and Vegas with \( \alpha^+ = 2475 \) packet/s. The slight difference for Vegas with \( \alpha^+ = 250 \) packet/s is because the difference \( \beta - \alpha \), needed for stability, is a non-negligible fraction of \( \alpha \).

To compare the fairness of FAST, Vegas with small \( \alpha^+ \) and Vegas with large \( \alpha^+ \), we use two different criteria. The first criterion considers the most disadvantaged node (as in [12]). In our case, it is the first node. Therefore, we consider the ratio of its source rate, \( x_1(n) \), to its fair rate which is \( c/n \) for the three cases. Figure 5 depicts the values for the first criterion for each of the three schemes as new flows arrive. The second criterion, proposed by Jain [5], involves all sources. It is also a measure within (0,1] and it is defined by

\[
F = \frac{(\sum_{i=1}^{n} x_i)^2}{n \sum_{i=1}^{n} x_i^2}.
\]

By (25), the case \( F = 1 \) reflects the situation where all flows are equal while the smaller the value of \( F \) is, the larger the differences between the flows are. The three curves resulting from
the second criteria are plotted in Figure 6. A very consistent message emerges from Figures 5 and 6. Fairness is adversely affected by the increase in the number of sources. Also, the larger $\alpha^+$ is, the more unfairly the first Vegas flow is treated, which is consistent with our analysis in the previous section. This is illustrated for a wider range of $\alpha^+$ in Figure 7.

Another disadvantage of Vegas is that it generally requires more buffer space than FAST. Moreover, the rate of increase of the required buffer size will be greater for larger $\alpha^+$, as is shown in Figure 8.

For completeness, we also simulated the pathological case of $\alpha^+ \gg c$. We consider 10 flows with $\alpha^+ = 2500$ packet/s sharing a 1Mbps bandwidth link with round trip propagation delay 40 ms. This gives $\alpha^+ = 20c$. The analysis shows that $p(i)$ should be roughly equal to $d(\alpha^+/c)^i$. Table 1 compares this approximation with both the simulated and the theoretical $p(i)$. Simulation results were only obtained for $i \leq 3$, due to the very large queue sizes involved. The 20% discrepancy between the theoretical and simulation results for the first source is because the measured baseRTT includes the 8 ms packetisation delay, which is 20% of the 40 ms propagation delay.
8 Conclusion

FAST TCP and TCP Vegas both adjust their rates based on the estimated propagation delay and the measured round trip time. If they both know their true propagation delays, then they have identical equilibrium rates and buffer occupancies. However, in the presence of estimation error, differences arise. In particular, the equilibrium of the prose form of Vegas differs from that of FAST and the form of Vegas commonly implemented. We have found expressions for the rates of different FAST and Vegas flows. In the particular case of persistent congestion, we have quantified the amount by which FAST is fairer than Vegas. In particular, the previous analysis of Vegas under persistent congestion [10] does not apply exactly to FAST or the implemented version of Vegas, and the unfairness due to persistent congestion is actually less severe than it predicts. In the analysis of [10], Vegas’s fairness is influenced by its parameter $\alpha^+$, whereas FAST’s fairness is independent of $\alpha$. The larger $\alpha^+$ is, the more unfairly Vegas will treat the old flows, which have an accurate estimate of their propagation delay. When $\alpha^+$ is small compared to the bottleneck link capacity, Vegas’s equilibrium is almost the same as that of FAST. However, in the extreme case of $\alpha^+ >> c$, Vegas becomes highly unfair, and the buffer occupancy increases geometrically. In contrast, for FAST and Vegas with small $\alpha^+$, we demonstrated numerically that the increase in queue size is of order $\log(i)$ as the $i$th flow arrives.
